## 1    **Abstract**

2    Inadequate representativeness of driving cycles used by regulatory in-lab tests is one  
3    significant factor leading to large discrepancy between real-world fuel consumption and  
4    type-approval levels. On-board measurement devices have been used in past researches  
5    to collect vehicle activity data but the amount of data is usually limited. With second-  
6    by-second GPS-informed trajectory data of 459 private passenger cars in place, covering  
7    over 17,000 sampling days, we enabled to use big-data mining techniques to study the  
8    variations in real-world driving cycles. A Markov chain method was developed to  
9    generate typical driving cycles that have similar properties as real-world driving. As  
10    case study, two typical driving cycles (i.e., Off-peak Cycle, Peak Cycle) are constructed  
11    from six sub-cycles representing different road types and traffic conditions, which depict  
12    fine-scale discrepancies of driving characteristics among different situations. Vehicle  
13    fuel consumption simulation results show that the developed typical driving cycle leads  
14    to up to 20% higher fuel consumption than regulation test cycles (i.e., NEDC, WLTC).  
15    This study constructed typical driving cycle from massive GPS trajectory data; the result  
16    highlights the discrepancy of vehicle energy consumption between real-world driving  
17    cycles and regulation test cycles and the importance to address real-world driving  
18    conditions in future regulation.
